Summary:

This note has shown that it is possible to estimate the area contaminated with THC > 50 mg/kg, and also to evaluate the changes in area size during a period of 10-15 years. Even though the number of stations around each installation has been reduced in the recent years, the contaminated area can still be estimated, and the results show that the contaminated areas have decreased from 50% to 90% at all installations. The reason why is not discussed in this note.

1 INTRODUCTION

DNV Consulting has been asked by OLF to prepare a note that describes a historical development of the total hydrocarbon content in sediments in the vicinity of selected installations in the Norwegian sector.

This note is based on environmental data from previous monitoring surveys carried out by oil companies from 1990 to 2002.

According to the Norwegian Activities regulations¹ regional environmental surveys shall be

carried out by the operators every third year. The Norwegian sector is divided into 11 regions, as shown in Figure 1.1. Biological, chemical and physical parameters are included in the survey.

Collected data are stored in a the MOD database (Environmental Monitoring Database), owned by OLF and operated by DNV.

A large cutting piles project has lately been carried out (UKOOA Drill Cuttings Initiative). One of the conclusions (regarding THC) was that the “THC is the key parameter regarding biological effects”, and that “50 mg THC/kg in sediments was considered to be the limit for contaminated areas”.

Based on these conclusions this note gives a brief summary of the THC contaminated area (> 50 mg/kg) for some selected installations in the Norwegian Sector. Rogalandsforskning (2000) has conducted a study to quantify the total amount of cuttings discharged on the Norwegian Continental Shelf. The study also intended to quantify residual cuttings materials left under/around the installations (see Appendix A). As shown by Rogalandsforskning the number of cuttings piles at Norwegian sector is higher than those presented in this report.

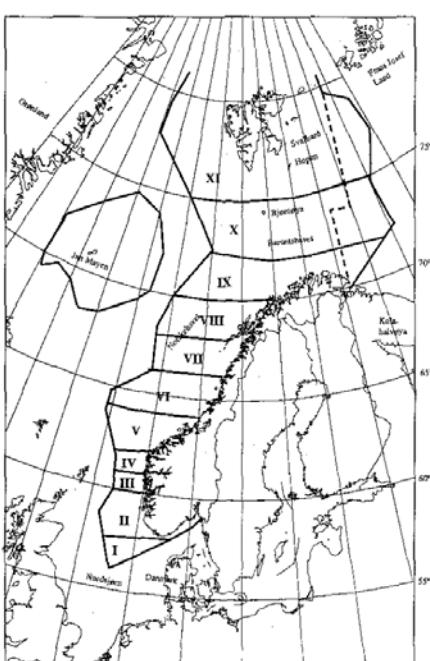

Figure 1.1. Overview of the 11 regions for sediment monitoring in the Norwegian sector.

TECHNICAL NOTE

2 MATERIAL AND METHODS

A contour and surface mapping program has been used to calculate the area contaminated with THC, (SURFER, version 8 from Golden Software). The accuracy of the contour plot is depending on the number of data available. If the number of sampling stations is low the accuracy of the estimation of contaminated area is also low. In the SURFER program a total of twelve different models with different properties can be used. The most suitable model to present our data (where the number of observations often is less than ten) is the *Kriging* model (see Appendix B for details). It is important to have in mind that all maps that have been drawn in this report only illustrate the major trends in the data. Ten or fewer points are not enough to define more than a general trend in the data. The other option when calculating the contaminated area is to calculate the radius represented by the stations that are contaminated. This can be difficult when the last station in a sampling grid (e.g. 1000m from the installation) is contaminated. The SURFER model will in such cases take into account neighbouring stations and calculate the trend in the data in a much better way.

In this note some examples of contour plots are shown for each field/installation, and in Appendix C all plots are enclosed.

Table 2-1 gives an overview of installations included in this note.

The sampling grid is normally designed with stations located 250m to 5000m from the installation in four different directions. If none of the stations are contaminated the minimum distance is by default set to be less than 250m, and the contaminated area calculated to $0.2 \text{ km}^2 (\pi r^2)$.

Table 2-1. Overview of installations included in this note.

3 RESULTS AND COMMENTS

3.1 Statfjord A

Contaminated area

Table 3-1 shows the THC concentrations from all stations at Statfjord A. Stations with concentrations > 50 mg/kg are marked with red colour. Some contour plots are given in Figure 3-1 (see Appendix C for all contour plots).

Table 3-1. THC content at Statfjord A (mg THC/kg sediments).

Comments

From 1990 to 1993 the sampling grid did not restricted the area contaminated with THC in the 310 degree direction. The sampling grid was also too small in 1994 and 1996 to give good estimate of the contaminated areas for those years. But both in 1999 and 2002 the surveys covered the whole area.

The reduction in contaminated area from 1993 to 2002 is estimated to be about 76% (se Table 3-2). The contaminated area from 1990 to 2002 is illustrated in Figure 3.1.

Table 3-2. Calculated area contaminated with THC > 50 mg/kg, Statfjord A.

Year	1990	1991	1992	1993	1994	1996	1999	2002
Area contaminated	5.2 km ²	4.5 km ²	1.1 km ²	6.7 km ²	4.4 km ²	4.7 km ²	2.9 km ²	1.6 km ²

TECHNICAL NOTE

Comments

The station grid established in 1990 covered the contaminated area. In 1990 nearly 7 km² was contaminated and in 2002 1.2 km² was contaminated (see Table 3-4).

Table 3-4. Calculated area (km²) contaminated with THC > 50 mg/kg at Statfjord B.

Year	1990	1991	1992	1993	1996	1999	2002

Comments

The maximum THC concentration decreased significantly from 1991 to 1992 (from 45 300 mg/kg to 18 800 mg/kg) at station SFC-1 (see Table 3-5). Generally, the stations covered the whole area very well. The contaminated area was at the highest in 1992 with 4.6 km², and decreased to 1.8 km² in 2002 (60% reduction), see Table 3-6.

Comments

The THC concentration at GFA-1 decreased significantly from 1990 to 1993, but was found to be high in 1996. Unfortunately this station was not followed up in the following surveys. The contaminated area decreased from 6.5 km² in 1990 to 0.2 in 1993 and in 1999 and 2002 (none of the stations was contaminated), but in 1996, due the high concentration at GFA-1, the contaminated area was calculated to more than 3 km².

Table 3-8. *Calculated area (km²) contaminated with THC > 50 mg/kg at Gullfaks A*

Year	1990	1991	1992	1993	1996	1999	2002
Area contaminated	6.5	2.5	1.7	0.2	3.1	0.2	0.2

Comments

The THC concentration was found to be high at station GFC-1 in 1991, decreasing until 1996, higher in 1999 and than low again in 2002. This also reflects the contaminated area, see Table 3-13.

The survey in 2002 included sampling stations from only one direction. To calculate the contaminated areas in 2002 is therefore impossible.

Table 3-13. *Calculated area (km²) contaminated with THC > 50 mg/kg at Gullfaks B.*

Comments

The area contaminated with THC was low in 1992, increasing to nearly 6 km² in 1994, and then reduced to 0.2 km² in 2001, see Table 3-15.

Comments

The THC concentration was extremely high at station OSEF-18 in 1991, with a significant decrease from 1991 to 1993. The extremely high concentration in 1991 can explain the “over-calculated” contaminated area in 1991. The contaminated area decreased from 1992, and increased in the period 1994 to 2001.

Comments

In 1992 the contaminated area was calculated to 2.5 km². In 1993 both the 2000m and 3500m stations were contaminated (with no stations outside these stations), and therefore it is impossible to calculate the contaminated area for that year, see Table 3-17.

Comments

In 1996 the contaminated area was calculated to 8,8 km². In 1996 only the 1000m and 4000m stations were sampled in the 254 degree direction. Since the 1000m station was contaminated the area was overestimated. With a “normal” value at 2000m the area had decreased to about 4,4 m². In 1999 only station VH-10 (164°/1000m) was contaminated with THC > 50 mg/kg. In 2002 station VH-3 and VH-08 were both contaminated with THC (> 50 mg/kg). In 1996 and 1999 the 2000m station (VH-04) was the closest in the 74° direction. A manual calculation (simply by making a circle based on contaminated station, and than calculate the area) gives the following areas: 1996 – 4,4 km²; 1999 – 3,8 km² and 2002 – 2,7 km², nearly 40% decrease.

Table 3-21. *Calculated area (km²) contaminated with THC > 50 mg/kg at Valhall.*

Year	1996	1999	2002
Area contaminated (SURFER)	8,8 ¹	0,6	3,5
Area contaminated (manually)	4,4	3,8	2,7

¹ Due to lack of one station in 164 degree direction. Would probable been around 4,4 if “all” stations was taken

TECHNICAL NOTE

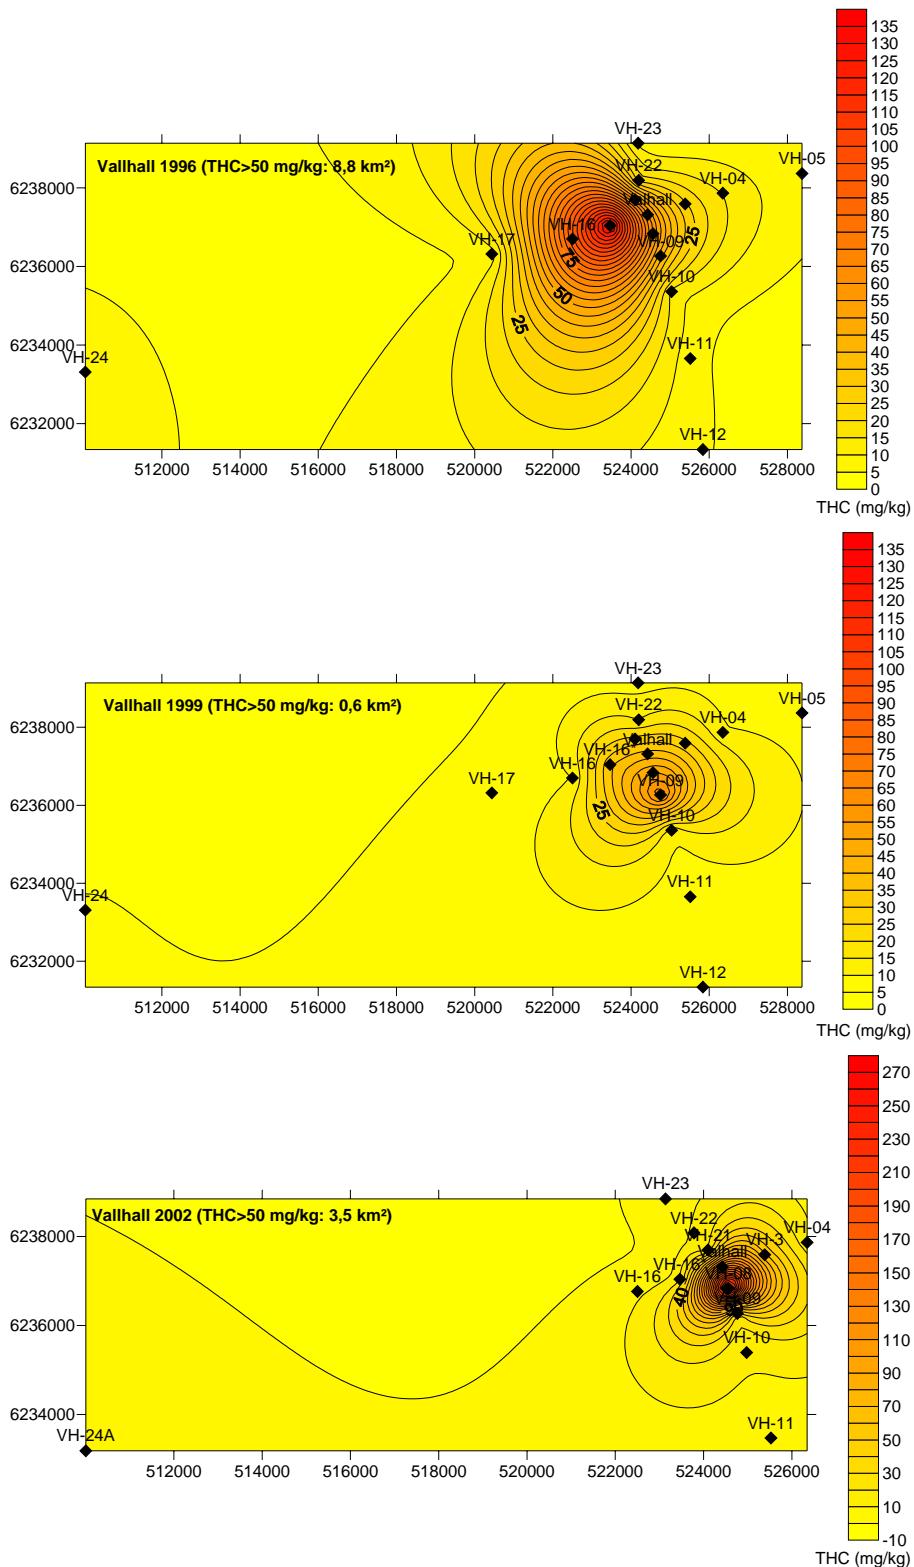

Figure 3-11. Contour plot of THC concentrations at Valhall in 1996 (above), 1999 (middle), and 2002(bottom)). 50 mg/kg concentration is marked as a red line in the plot. Note the difference in the scale.

3.11 Ekofisk 2/4A

Contaminated area

DNV carried out a characterisation of the cutting pile at Ekofisk 2/4A in 2002 (DNV 2003). An extract from the report is given here.

The shape of the cuttings pile was measured using a ROV, and a contour plot of the bottom surface is shown in Figure 3-12 and compared with earlier depth measurements.

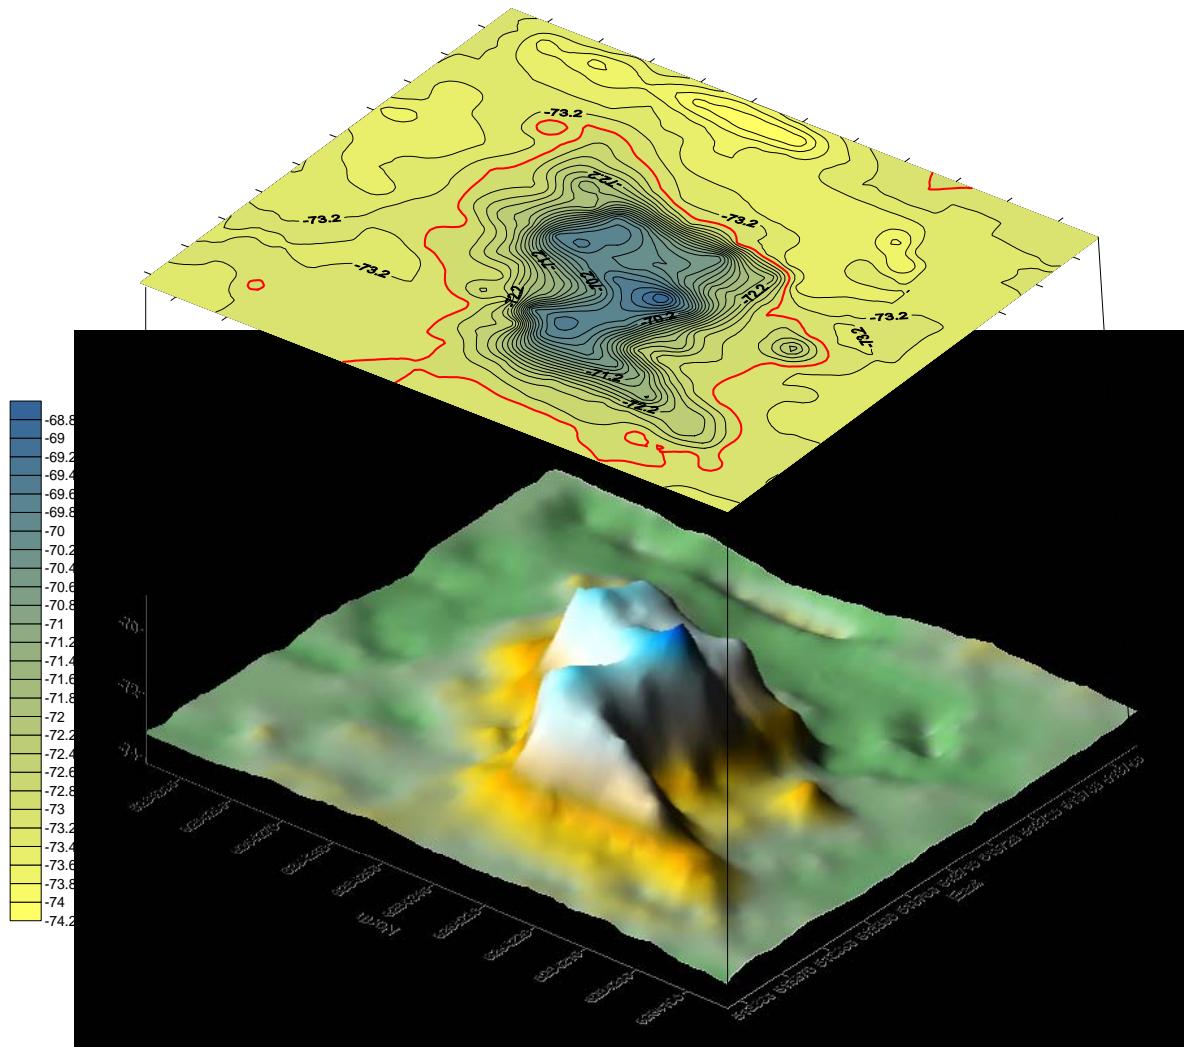

Figure 3-12. Depth contour of the cuttings pile area. Note that the depth intervals are in meter and length intervals in 10meters (1:10 ratio). The boundary of the cuttings pile is set to 73m (depth contour, shown as a red boundary in the upper map).

TECHNICAL NOTE

Comparing the estimated volumes¹ of the cuttings pile in 1998 and 2002 shows that the pile had decreased by approx. 20% from 1998 to 2002, see

Table 3-22. Depth measuring was done during ROV surveys, and since different echosounders were used, the calculations are subject to some uncertainty (maximum depth in 1998 was 74.0 and in 2002 74.2m). This is considered to be a minor difference. The volume is calculated as everything above "ground level", and the differences in pile volume in 1998 and 2002 turned out the same when varying the ground level from 72 – 73.5m, see Table 3-19. This means that the reduction of the cuttings pile has been considerable the last four years, probably due to erosion. The water depth at the highest point of the pile has increased from 67.5m in 1998 to 68.7m depth in 2002, i.e. the top of the pile has been reduced by approx. 1.2m. This is a reasonable reduction based on RF's estimated relationship between pile height and length of time the pile has been dormant (RF 1999), which was 26 cm per year. In the same study the erosion rate at Ekofisk 2/4 A was estimated to be 158 m³/yr.

Table 3-22. Volume of the cuttings pile calculated from ROV surveys at Ekofisk 2/4 A in 1998 and 2002.

Cutting piles depth	Volume (m ³) 1998	Volume (m ³) 2002	Reduced volume
72m	2519	2041	(19%)
72,5m	3719	2962	(20%)
73m	5569	4374	(21%)
73,5m	9996	8082	(19%)

In Figure 3-13 the THC concentrations based on all stations are plotted as a contour plot. The area with concentrations > 50 mg/kg is calculated to 0.25 km².

It is possible to compare this area with the 1999-regional survey. The total area with concentrations > 50 mg/kg was 0.58 m² in 1999, see Figure 3-13. Thus the contaminated area (> 50 mg THC/kg) has decreased from 0.58 m² in 1999 to 0.25m² in 2002.

¹ The estimated volume differs from the volume calculated by RF in 1999 because of different methods of calculation (the estimated volumes will vary with the definition of the "ground floor" etc.). In the current comparison the RF and DNV data from 1998 and 2002 respectively have been utilised in the same manner.

TECHNICAL NOTE

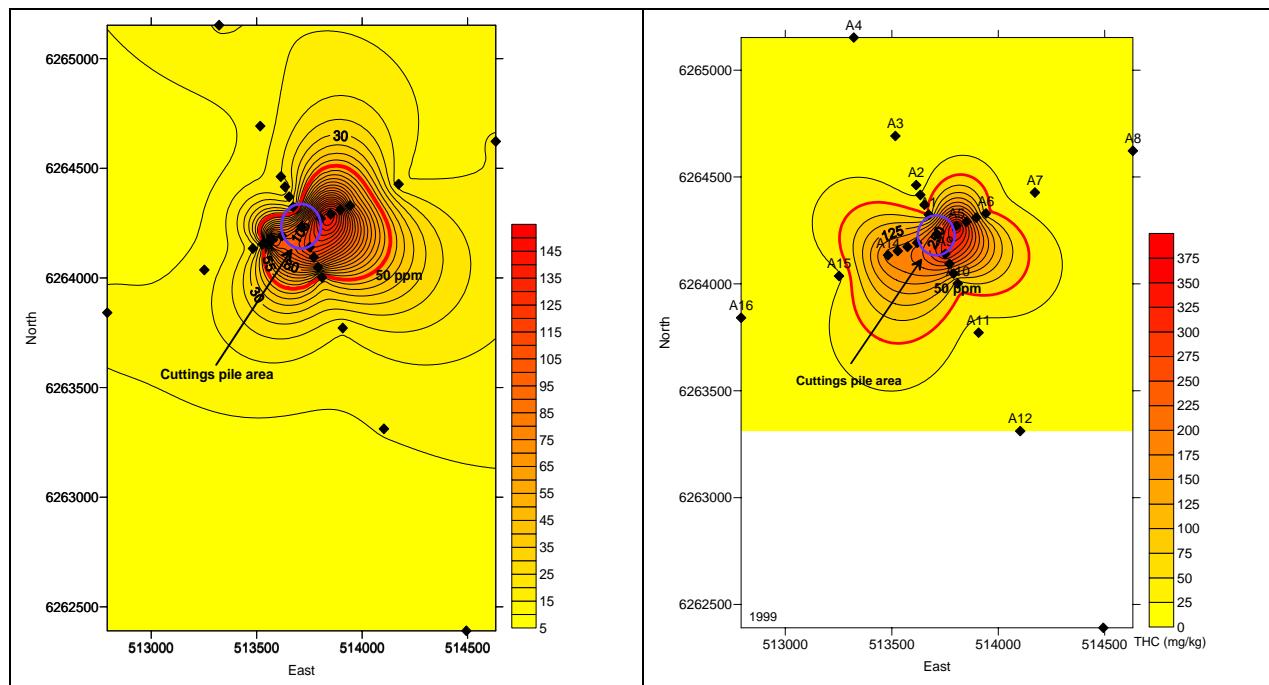

Figure 3-13. Area contaminated with THC (red line is the 50 mg/kg boundary and the blue circle represents the cuttings pile), 1999 (left) and 2002(right).

3.12 Conclusions

This note has shown that it is possible to estimate the area contaminated with THC > 50 mg/kg, and also to evaluate the change in area size during a period of 10-15 years. Even though the number of stations around each installation has been reduced in the recent years, the reduced area can still be estimated, see Table 3-17. The results show that the contaminated areas have decreased from 50% to 90% at all installations. The reason why has not been discussed in this note, but the reductions should be compared with the discharges and the THC concentration in deeper layer of the sediments.

APPENDIX

A

CUTTINGS DATA

Appendix 1. Cuttings data

Rogalandsforskning (2000) has conducted a study to quantity the total amount of cuttings discharged on the Norwegian Continental Shelf. The study also intended to quantify residual cuttings materials left under/around the installations. The latter task was attempted by means of using data from mapped piles and applying these to all fields, and by using existing models (from Ekofisk and UKOOA R&D). It was concluded to be an impossible task based on available data.

For this study however it is considered important to have at least an estimate of the amount of cuttings piles materials left around the installations. The uncertainty in the data is recognised, but a conservative approach is taken to allow for an evaluation of a reasonable “Worst case” scenario. The wording “reasonable” then refers to a process of making the best evaluation of the data for the individual fields with regard to discharge history, water depth and location.

Among the factors considered important are:

- Type of discharge (WBM, OBM, PBM)
- Discharge regime (over board, dumping liner, at seabed)
- Field structure (fixed installation, floater/pre-drilling, satellite)
- Time since discharge
- Geographical location
- Water depth
- Currents

Since the scope of the present study does not include these calculations (supposed to be an input to the study) only a coarse evaluation based on the above factors is made.

The few piles that have been mapped give some indications on the order of magnitude of materials remaining versus that discharged. There is no scientific documentation for this, but it seems to be fair to generally accept that in the order of 20% material is left at a “normal” field. This number also corresponds well with results from the models available (UKOOA and Ekofisk). Based on this, every single field is evaluated on the above parameters and with the indicative percentile as a basis. Large water depth and the use of water based mud are the two most important factors reducing the percentile, oil based mud and low water depth the two single parameters increasing the percentile most. Anyway, this exercise is done to produce input data for the onshore evaluation, and the individual field data are less important. The cuttings data listed below should therefore not be cited or used for any other purpose than this.

To make the data workable for the onshore processing capability evaluation, a split into 5 year time intervals is made. This is based on a subjective evaluation of the time of field cessation, assuming possible cuttings removal to be phased with this activity.

This is only done with respect to fields where OBM or PBM are used (partly or fully).

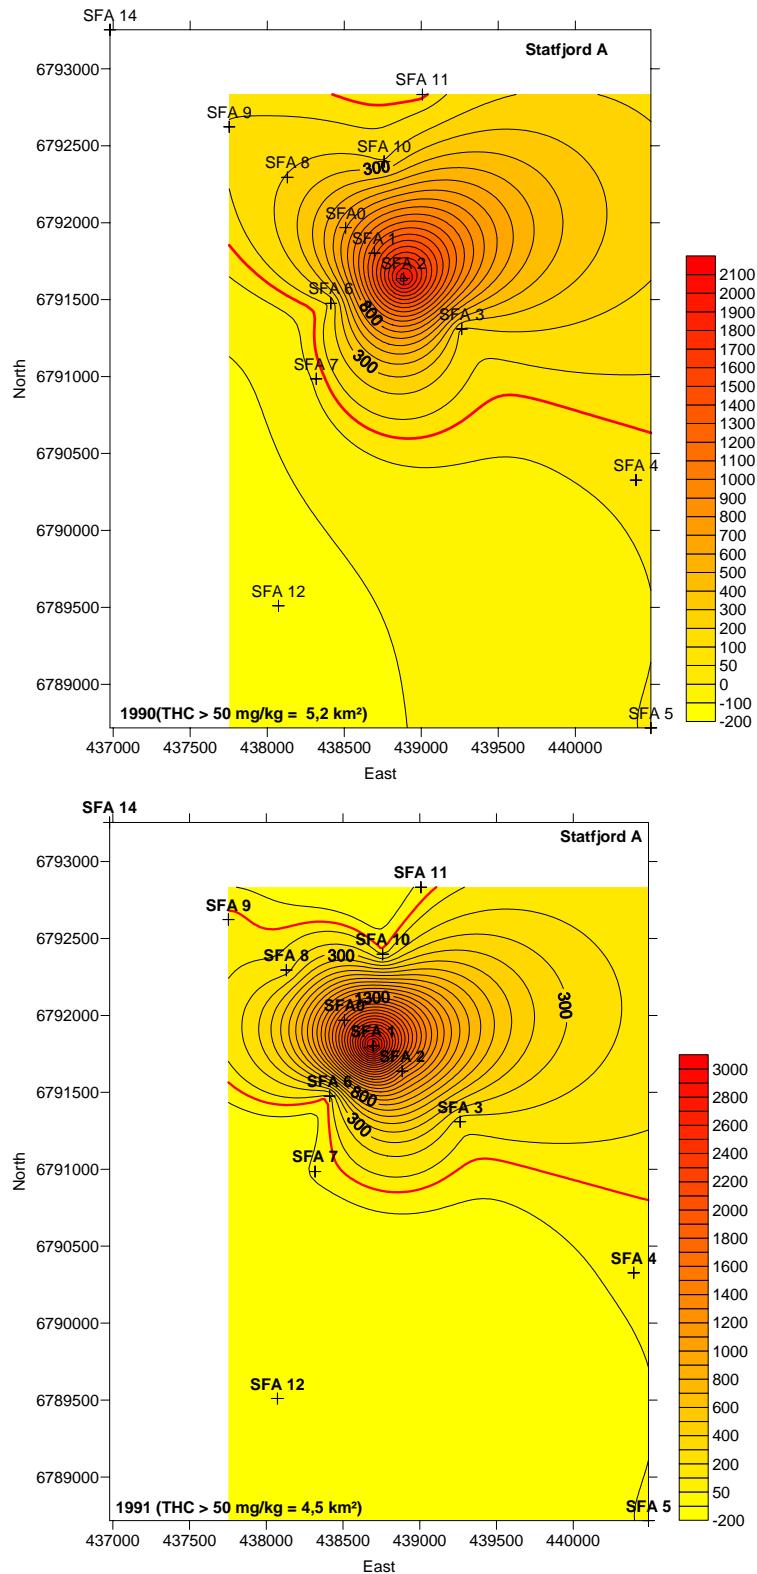

Table 3-24 Data for estimating remaining amount of cuttings material at individual fields.

Field	Volume (m ³)	Depth (m)	Drill fluid	More/less than av	Remaining	Pile?	Comment
